

# Interprocess communication

- in Operating systems we find there are a number of mechanisms used for interprocess communication (IPC)
- the IPC mechanisms can be divided into two groups, those which work well using shared memory and those which work with non shared memory
- some common methods of IPC are: sockets, semaphores and mailboxes
- sockets and mailboxes are normally used by non shared memory programs
  - ie client and server on different machines

# Interprocess communication in shared memory systems

- semaphores are more appropriate for multiple processes sharing some common memory
- we will be covering a semaphores and message passing after networking with sockets
- message passing
  - can be used in shared memory systems
- this week we will look at Semaphores

## Semaphores: shared memory interprocess communication

- processes within an operating system do not act in isolation
  - on the one hand they co-operate to implement an application
  - on the other hand they compete for resources, processor time, device access etc
  
- these two elements of co-operation and competition imply some form of communication between the processes

# Semaphores: shared memory interprocess communication

- in effect there are two categories for interprocess communication
  - **mutual exclusion**
  - **synchronisation**
  
- **mutual exclusion**
  - some resources in an operating system are non sharable, maybe access to the sound card or access to the GPU
  - access needs to be granted to one process at a time
  
- **synchronisation**
  - processes run asynchronously relative to each other
  - sometimes there will be points beyond which a process cannot proceed until another process has completed some activity

# Mutual exclusion

- require a mechanism to ensure that only one process can manipulate data at any one time
  - *mutual exclusion*
- the concepts we discuss today are *very* important for operating systems
  - a fundamental building block

## How do we implement mutual exclusion?

- simplest mechanism
  - mask processor interrupts off
  - processor cannot respond to any interrupt and therefore will execute code in sequence until it masks interrupt back on again
  - sometimes these critical sections of code are called *atomic*
  - what are this disadvantages with this approach?
  - what are this advantages with this approach?

## How do we implement mutual exclusion?

- another mechanism is *semaphores*
  - essentially a binary *semaphore* is a token which can be grabbed by *only one* process at a time
  - a token is taken at the entry to the critical section and given back at the end of the critical section
  - a process can only enter once it has the token

# Semaphores

- the most important single contribution towards interprocess communication was the introduction of **semaphores** by E.W. Dijkstra in 1965
  - a semaphore is a data type and the primitive operators are `wait` and `signal`
- these are the classic operators translated from Dutch words

# Semaphores

- consider the following two processes:

- ```
/* Shared semaphore */
Semaphore token; /* initial value 1 */

void ProcessA ()      void ProcessB ()
{
    while (TRUE) {
        ...
        Wait(Token)
        /* critical
           region */

        Signal(Token)
        ...
    }
}

{
    while (TRUE) {
        ...
        Wait(Token)
        /* critical
           region */

        Signal(Token)
        ...
    }
}
```

# Semaphores

- "SEMAPHORE token" at 0.906,8.919 ljust circle at 3.150,8.925 rad 0.656
- Wait gets the token
- Signal returns the token

# Semaphores

- note that `Wait` and `Signal` are both *atomic*
- they are implemented in software with processor interrupts masked off
- this allows us to build critical regions which can execute with processor interrupts on
- this is overall efficient as we only have to mask processor interrupts off during the execution of `Wait` and `Signal`
  - this time should be short compared with the time to execute the critical region

# Semaphores

- we can express Wait and Signal in pseudo code:

```
void Wait (s)
{
    when s>0
        s--;
}

void Signal (s)
{
    s++;
}
```

# Semaphores

- in our previous example the initial value of s would be 1
  - note that this is pseudo code
  - note the use of **when**

# Semaphores

- we have now seen how a critical section can be achieved by using semaphore primitives `Wait` and `Signal`
- for example access to the shared buffer will be a critical section

## Starting to implement a shared buffer using semaphores

```
void put (char ch)      char get (void)
{
    Wait (Mutex)        {
    /* safe to alter */  /* safe to alter */
    /* buffer           */ /* buffer           */
    place ch into buf    remove ch from buf

    Signal (Mutex)       Signal (Mutex)

                           return ch;
    }

    char buffer[Max];    /* global data */
    SEMAPHORE Mutex;     /* global data */
```

■ we will return to this code next week

# Implementing synchronisation with a Semaphore

```
void ProcessA ()
{
    while (TRUE) {
        ...
        Wait(sync)
        /* process B reached
           point B.  */
        ...
    }
}

void ProcessB ()
{
    while (TRUE) {
        ...
        /* point B */
        Signal(sync)
        ...
    }
}
```

# Python Semaphores and Threads

- in python you can create threads and create semaphores
  - there are a number of Python primitives which operate on semaphores but we will concentrate on those which map onto `Wait` and `Signal`

# Python Semaphores and Threads

- semaphores can be created and used by:

- ```
from thread import start_new
from threading import Semaphore

Mutex = Semaphore(value=1)

Mutex.acquire() # Wait

Mutex.release() # Signal
```

- a thread can be created by using `start_new`

# Example in Python of two threads synchronising

`simplesync.py`

```
#!/usr/bin/env python

import sys, time
from thread import start_new
from threading import Semaphore

sync = Semaphore(value=0)

def processA (p, count):
    global sync
    print "processA", p, "comes to life"
    while True:
        time.sleep (5)    # do some work
        sync.release()    # indicate we have finished our work
```

# Example in Python of two threads synchronising

`simplesync.py`

```
def processB (p, count):
    global sync
    print "processB", p, "comes to life"
    while True:
        print "waiting for process A to complete its work"
        start_time = time.time()
        sync.acquire()
        end_time = time.time()
        print "processB", p, "spent", end_time - start_time, "seconds waiting to for pr

def main ():
    start_new(processA, (1, 0))
    processB (2, 0)

main ()
```

## Example in Python of two threads implementing mutual exclusion

**simplemutex.py**

```
#!/usr/bin/env python

import sys, time
from thread import start_new
from threading import Semaphore

mutex = Semaphore(value=1)
n = 0 # global variable which will be incremented and
      # decremented inside the critical region
```

# Example in Python of two threads implementing mutual exclusion

simplemutex.py

```
def process (p, count):
    global mutex, n
    print "process", p, "comes to life"
    while True:
        start_time = time.time()
        print "process", p, "waiting to enter"
        mutex.acquire()
        end_time = time.time()
        print "process", p, "spent", end_time - start_time, "seconds waiting to enter the critical region"
        # critical region
        n += 1
        if n != 1:
            print "something has gone very wrong!"
            sys.exit (1)
        time.sleep (5)
        n -= 1
        mutex.release()
    print "process", p, "finished critical region"
```

## Example in Python of two threads implementing mutual exclusion

**simplemutex.py**

```
def main ():  
    for i in range (3):  
        start_new(process, (i, 0))  
    process (4, 0)  
  
main ()
```
